

the usual random-effects fit

one patient, one set of observations

The likelihood factors over patients, and each patient's own scatter is what identifies the population spread.

here

the cohort's patients: *never observed*

Nothing factors. A row is a functional of the whole cohort, computed by someone else, under their own eligibility rule and their own assay.

3 rows

what the paper printed

median	4.1
$\hat{q}_{0.25}, \hat{q}_{0.75}$	2.8, 6.0
